

## **Compression Programs**

- File Compression: Gzip, Bzip
- Archivers : Arc, Pkzip, Winrar, ...
- File Systems: NTFS

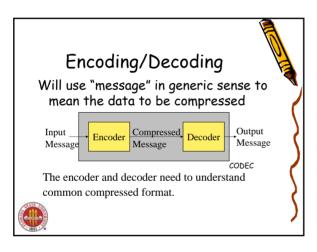

#### Multimedia

- HDTV (Mpeg 4)
- Sound (Mp3)
- Images (Jpeg)

### **Compression Outline**

Introduction: Lossy vs. Lossless Information Theory: Entropy, etc. Probability Coding: Huffman + Arithmetic Coding

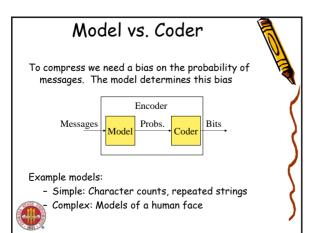

#### Lossless Compression Techniques

- $\cdot$  LZW (Lempel-Ziv-Welch) compression
  - Build dictionary
- Replace patterns with index of dict.
- Burrows-Wheeler transform
  - Block sort data to improve compression
- Run length encoding
  Find & compress repetitive sequences
- Huffman code
  - Use variable length codes based on frequency

How much can we compress?

For lossless compression, assuming all input messages are valid, if even one string is compressed, some other must expand.

# Quality of Compression

Runtime vs. Compression vs. Generality Several standard corpuses to compare algorithms

#### Calgary Corpus

- 2 books, 5 papers, 1 bibliography,
  - 1 collection of news articles, 3 programs,
  - 1 terminal session, 2 object files,
  - 1 geophysical data, 1 bitmap bw image
- The <u>Archive Comparison Test</u> maintains a comparison of just about all algorithms publicly available

## Comparison of Algorithms

Program	Algorithm	Time	BPC	Score
BOA	PPM Var.	94+97	1.91	407
PPMD	PPM	11 + 20	2.07	265
IMP	BW	10+3	2.14	254
BZIP	BW	20+6	2.19	273
GZIP	LZ77 Var.	19+5	2.59	318
LZ77	LZ77	?	3.94	?

## Information Theory

An interface between modeling and coding

- Entropy
  - A measure of information content
- Entropy of the English Language
  - How much information does each character in "typical" English text contain?

# Entropy (Shannon 1948)

For a set of messages S with probability p(s),  $s \in S$ , the <u>self information</u> of s is:

$$i(s) = \log \frac{1}{p(s)} = -\log p(s)$$

Measured in bits if the log is base 2.

The lower the probability, the higher the information

<u>Entropy</u> is the weighted average of self information.

$$H(S) = \sum_{s \in S} p(s) \log \frac{1}{p(s)}$$

#### Entropy Example

 $p(S) = \{.25, .25, .25, .125, .125\}$  $H(S) = 3.25 \log 4 + 2.125 \log 8 = 2.25$ 

 $p(S) = \{5,.125,.125,.125,.125\}$  $H(S) = .5 \log 2 + 4 \cdot .125 \log 8 = 2$ 

 $p(S) = \{.75, .0625, .0625, .0625, .0625\}$  $H(S) = .75 \log(4/3) + 4 \cdot .0625 \log 16 = 1.3$ 

#### Entropy of the English Language How can we measure the information per character? ASCII code = 7 Entropy = 4.5 (based on character probabilities) Huffman codes (average) = 4.7 Unix Compress = 3.5 Gzip = 2.5 BOA = 1.9 (current close to best text compressor) Must be less than 1.9.

Asked hum given the these as estimate Language		ous t orobo of t	ie ne text abili <sup>:</sup> he E	ext o . He ties Engli	char e use to ish	ed		
	er of guesses							Ì
unswer	# of guesses					5		- \
	Probability	.79	.08	.03	.02	.02	.05	J
From the experiment he predicted H(English) = .6-1.3								<b>\</b>

## Assumptions

Communication (or file) broken up into pieces called messages.

Adjacent messages might be of a different types and come from a different probability distributions

#### We will consider two types of coding:

- **Discrete**: each message is a fixed set of bits - Huffman coding, Shannon-Fano coding
- Blended: bits can be "shared" among messages

- Arithmetic coding

## Uniquely Decodable Codes

- A <u>variable length code</u> assigns a bit string (codeword) of variable length to every message value
- e.g. a = 1, b = 01, c = 101, d = 011 What if you get the sequence of bits 1011?
- Is it aba, ca, or, ad?
- A <u>uniquely decodable code</u> is a variable length code in which bit strings can always be uniquely decomposed into its codewords.

# Prefix Codes A <u>prefix code</u> is a variable length code in which no codeword is a prefix of another word e.g a = 0, b = 110, c = 111, d = 10 Can be viewed as a binary tree with message values at the leaves and 0 or 1s on the edges.

	Some	Prefix	Codes f	or Integers		
	n	Binary	Unary	Split		
	1	001	0	1		
	2	010	10	10 0		
	3	011	110	10 1		
	4	100	1110	110 00		
	5	101	11110	110 01		
	6	110	111110	110 10		
Many other fixed prefix codes: Golomb, phased-binary, subexponential,						

#### Average Bit Length

For a code C with associated probabilities p(c) the **average length** is defined as

$$ABL(C) = \sum_{c \in C} p(c)l(c)$$

We say that a prefix code C is <u>optimal</u> if for all prefix codes C',  $ABL(C) \le ABL(C')$ 

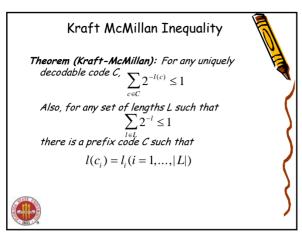

## Relationship to Entropy

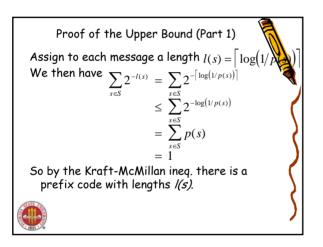

**Theorem (lower bound):** For any probability distribution p(S) with associated uniquely decodable code C,

 $H(S) \leq ABL(C)$ 

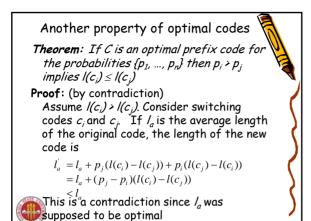

**Theorem (upper bound):** For any probability distribution p(S) with associated <u>optimal</u> prefix code C,

 $ABL(C) \le H(S) + 1$ 

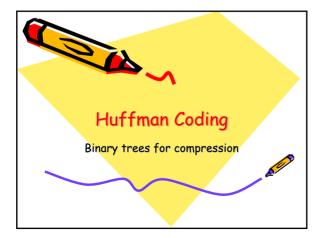

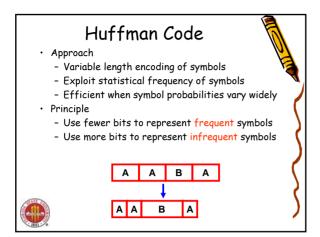

#### Huffman Codes

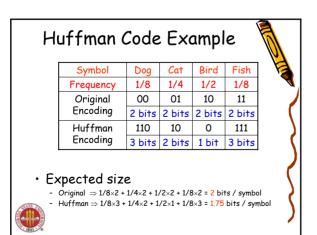

Invented by Huffman as a class assignment in 1950.

Used in many, if not most compression algorithms

• gzip, bzip, jpeg (as option), fax compression,...

#### **Properties:**

- Generates optimal prefix codes
- Cheap to generate codes
- Cheap to encode and decode
- *I<sub>a</sub>=H* if probabilities are powers of 2

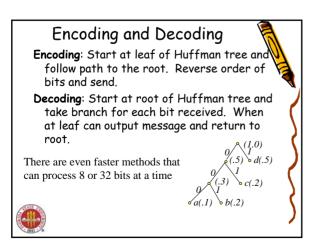

# Huffman Codes

Huffman Algorithm

- Start with a forest of trees each consisting of a single vertex corresponding to a message s and with weight p(s)
- Repeat:
  - Select two trees with minimum weight roots  $p_1$  and  $p_2$
  - Join into single tree by adding root with weight  $p_1 + p_2$

Example p(a) = .1, p(b) = .2, p(c) = .2, p(d) = .5• a(.1) • b(.2) • c(.2) • d(.5) (.3)0(5) (1.0) $\sqrt{d(.5)}$ (5)  $\bullet a(.1) \bullet b(.2)$ (.3) Step 1 a(.1) b(.2)(3) ℃(.2) Step 2 a(.1) b(.2)Step 3 a=000, b=001, c=01, d=1

#### Lemmas

- L1: Let p<sub>i</sub> be the smallest over the code, then l(c<sub>i</sub>) is the largest and hence a leaf of the tree. ( Let its parent be u)
- L2 : If  $p_j$  is second smallest over the code, then  $l(c_j)$  is the child of u in the optimal code.
- L3<sup>°</sup>: There is an optimal prefix code with corresponding tree T\*, in which the two lowest frequency letters are siblings.

# Huffman codes are optimal

**Theorem:** The Huffman algorithm generates an optimal prefix code. In other words: It achieves the minimum average number of bits per letter of any prefix code.

#### Proof: By induction

Base Case: Trivial (one bit optimal) Assumption: The method is optimal for all alphabets of size k-1.

#### Proof:

- Let y\* and z\* be the two lowest frequency letters merged in w\*. Let T be the tree before merging and T' after merging.
- Then :  $ABL(T') = ABL(T) p(w^*)$
- T' is optimal by induction.

## Proof:

- Let Z be a better tree compared to T produced using Huffman's alg.
- Implies ABL(Z) < ABL(T)</li>
- By lemma L3, there is such a tree Z' in which the leaves representing y\* and z\* are siblings (and has same ABL as Z).
- By previous page ABL(Z') = ABL(Z) p(w\*)
- Contradiction!

## Adaptive Huffman Codes

Huffman codes can be made to be adaptive without completely recalculating the tree on each step.

- Can account for changing probabilities
- Small changes in probability, typically make small changes to the Huffman tree

Used frequently in practice

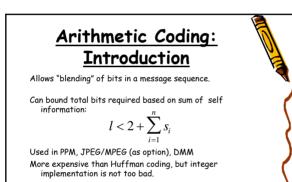

## Huffman Coding Disadvantages

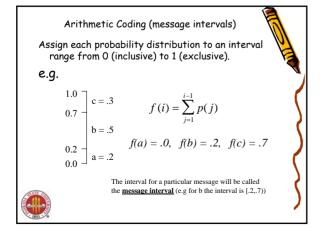

- Integral number of bits in each code.
- If the entropy of a given character is 2.2 bits, the Huffman code for that character must be either 2 or 3 bits , not 2.2.

# Towards Arithmetic coding

- An Example: Consider sending a message of length 1000 each with having probability .999
- Self information of each message -log(.999)= .00144 bits
- Sum of self information = 1.4 bits.
- Huffman coding will take at least 1k bits.
- Arithmetic coding = 3 bits!

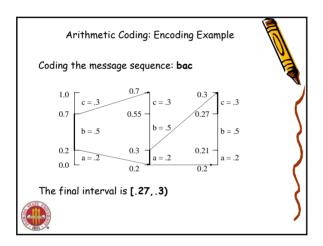

Arithmetic Coding (sequence intervals) To code a message use the following:  $l_1 = f_1$ ,  $l_i = l_{i-1} + s_{i-1}f_i$ 

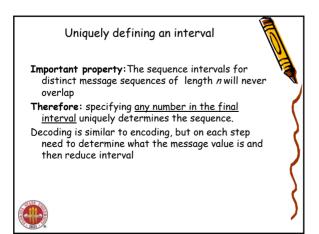

$$s_1 = p_1$$
  $s_i = s_{i-1}p_i$ 

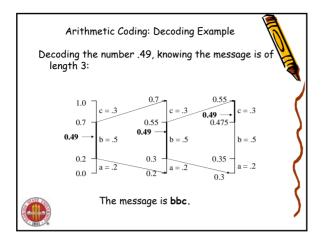

Each message narrows the interval by a factor of  $p_r$ . Final interval size:

$$s_n = \prod_{i=1}^n p_i$$

The interval for a message sequence will be called **sequence interval** 

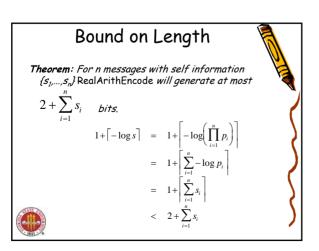

# **RealArith** Encoding and Decoding

#### **RealArithEncode:**

- + Determine /and  $\emph{s}$  using original recurrences
- Code using / + s/2 truncated to  $1+\left[-\log s\right]$  bits

#### RealArithDecode:

- Read bits as needed so code interval falls within a message interval, and then narrow sequence interval.
- Repeat until *n* messages have been decoded .

## Applications of **Probability Coding**

How do we generate the probabilities? Using character frequencies directly does not work very well (e.g. 4.5 bits/char for text).

#### Technique 1: transforming the data

- Run length coding (ITU Fax standard)
- Move-to-front coding (Used in Burrows-Wheeler)
- Residual coding (JPEG LS)

#### Technique 2: using conditional probabilities

- Fixed context (JBIG...almost)
- Partial matching (PPM)

## Run Length Coding Code by specifying message value followed by number of repeated

values:

#### e.g. abbbaacccca => (a,1),(b,3),(a,2),(c,4),(a,1)

The characters and counts can be coded based on frequency.

This allows for small number of bits overhead for low counts such as 1.

#### Facsimile ITU T4 (Group 3)

Standard used by all home Fax Machines ITU = International Telecommunications Standard Run length encodes sequences of black+white pixels Fixed Huffman Code for all documents. e.g.

White	Black
000111	010
0111	11
00111	0000100
	000111 0111

Since alternate black and white, no need for values.

## Move to Front Coding

Transforms message sequence into sequence of integers, that can then be probability coded Start with values in a total order:

e.g.: [a,b,c,d,e,....]

For each message output position in the order and then move to the front of the order. e.g.: c => output: 3, new order: [c,a,b,d,e,...]

a => output: 2, new order: [a,c,b,d,e,...] Codes well if there are concentrations of message

values in the message sequence.

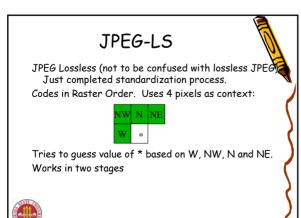

# **Residual** Coding

Used for message values with meaningfull order e.g. integers or floats.

**Basic Idea:** guess next value based on current context. Output difference between guess and actual value. Use probability code on the output.

JPEG LS: Stage 1	
Uses the following equation:	
$(\min(N,W))$ if $NW \ge \max(N,W)$	
$P = \begin{cases} \min(N, W) & \text{if } NW \ge \max(N, W) \\ \max(N, W) & \text{if } NW < \min(N, W) \\ N + W - NW & \text{otherwise} \end{cases}$	
N + W - NW otherwise	\
Averages neighbors and captures edges. e.g.	(
	)
40 3 * 30 40 * 3 3 *	(
40 3 20 30 40 40	<u>}</u>
	)

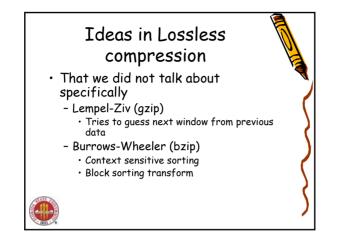

#### JPEG LS: Stage 2

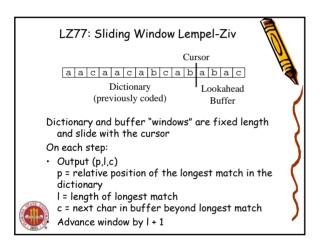

Uses 3 gradients: W-NW, NW-N, N-NE

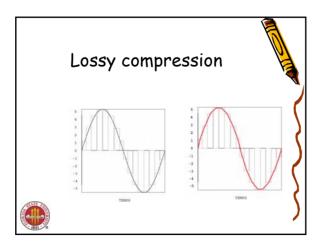

- Classifies each into one of 9 categories.
- This gives 9<sup>3</sup>=729 contexts, of which only 365 are needed because of symmetry.
- Each context has a bias term that is used to adjust the previous prediction
- After correction, the residual between guessed and actual value is found and coded using a Golomblike code.

# Using Conditional Probabilities: PPM

Use previous k characters as the context. Base probabilities on counts: e.g. if seen th 12 times followed by e 7 times, then the conditional probability *p(e(th)=*7/12. Need to keep k small so that dictionary does not get too large.

## Scalar Quatization

- Given a camera image with 12bit color, make it 4-bit grey scale.
- Uniform Vs Non-Uniform Quantization
  - The eye is more sensitive to low values of red compared to high values.

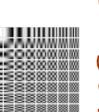

#### Vector Quantization

- How do we compress a color image (r,g,b)?
  - Find k representative points for all colors
  - For every pixel, output the nearest representative
  - If the points are clustered around the representatives, the residuals are small and hence probability coding will work well.

Transform coding

- Transform input into another space.
- One form of transform is to choose a set of basis functions.
- JPEG/MPEG both use this idea.

# Other Transform codes

- Wavelets
- Fractal base compression
  - Based on the idea of fixed points of functions.
